

# Reinforcement-Learned Multi-Source Transductive Foundation Models for Few-Shot Remote Sensing and Water Resources Monitoring

Ahmad Nawaz Zaheer, Muhammad Farhan

**Abstract**—Continuous planetary monitoring of inland water bodies, reservoir storages, river networks, and catastrophic flood inundation is indispensable for global water security, agricultural resource planning, and emergency disaster mitigation. While recent Earth observation foundation models—including vision-language models (e.g., GeoRSCLIP, RemoteCLIP) and self-supervised vision transformers (e.g., DINOv3, SatMAE)—provide rich generic representations, transferring them to specialized hydrological targets with scarce labeled data remains a formidable challenge. In operational disaster response, transductive inference is particularly compelling because satellite imagery is acquired in large spatial scenes that can be inferred jointly as an unlabeled query batch. However, existing transductive information maximization techniques rely on rigid, handcrafted heuristics: static neighborhood sizes ( $\kappa = 5$ ), uniform edge weights, and invariant hyperparameter trajectories that fail under intricate hydrological topologies (e.g., narrow braided channels, shallow wetlands) and severe atmospheric cloud degradation. In this paper, we propose RL-HYDROFM (Reinforcement-Learned Hydro Foundation Model Adaptation), a novel framework that formulates transductive neighborhood graph construction and multi-source foundation model fusion as a policy-driven decision process. An Actor-Critic graph policy observes zero-shot predictive entropy, local topological density, and cross-modal optical-SAR concordance to dynamically assign sample-wise neighborhood cardinalities ( $\kappa_i \in \{1, 3, 5, 8, 12, 16\}$ ), confidence-calibrated consistency weights ( $\lambda_{LC,i} \in [0, 1]$ ), and multi-modal routing coefficients ( $\beta_i \in \Delta^1$ ) across complementary optical (GeoRSCLIP/Sentinel-2) and microwave radar (Sentinel-1 SAR/DINOv3) encoders. The resulting dynamic regularizers enter directly into closed-form Alternating Direction Method (ADM) iterations, introducing zero gradient backpropagation into the frozen foundation backbones and maintaining sub-second inference speeds. Extensive experiments on four dedicated Earth observation water benchmarks—EuroSAT-Water, Kaggle Sentinel-2 Water Bodies, Sen12-Flood, and RESISC45-Water—demonstrate that RL-HYDROFM consistently outperforms ten representative inductive, training-free, and transductive baselines (including Zero-Shot, ProtoNet, LP++, Tip-Adapter, Laplacian-Shot, TransCLIP, TIM++, and LC-TIM), achieving up to +6.5% top-1 accuracy gains in the extreme low-shot regime (1-shot and 2-shot) while exhibiting exceptional cloud-penetrating resilience during catastrophic weather events.

**Index Terms**—Earth observation, geospatial foundation models, reinforcement learning, transductive few-shot learning, wa-

ter resources monitoring, flood mapping, multi-source fusion, Sentinel-1/Sentinel-2, vision-language models.

## I. INTRODUCTION

FRESHWATER ecosystems, inland water bodies, transboundary river networks, natural wetlands, and artificial storage reservoirs sustain terrestrial biodiversity, global agricultural irrigation, municipal drinking supplies, and industrial activity [1], [2]. Over the past two decades, accelerating climate change, rapid demographic expansion, urban encroachment into vulnerable floodplains, and extreme hydro-meteorological shocks have exerted unprecedented strain on planetary water systems [3]. Surface water bodies exhibit profound spatial and temporal variability, ranging from gradual seasonal shoreline shrinkage in arid endorheic basins to rapid, catastrophic flood inundation triggered by intense cloudbursts, tropical cyclones, atmospheric rivers, and dam breach crises [4], [5]. In emergency disaster response operations, rapid, high-resolution, and accurate mapping of standing water, inundated infrastructure, and river overflows is vital for guiding life-saving humanitarian logistics, civil defense evacuations, and post-disaster structural damage appraisal [6].

According to international disaster databases (e.g., CRED EM-DAT and UN-SPIDER reports), hydrological disasters account for over 44% of all natural disasters worldwide, causing tens of thousands of fatalities and exceeding \$50 billion in annual direct economic losses. Achieving the United Nations Sustainable Development Goal 6 (Target 6.6: Protect and restore water-related ecosystems) and Goal 13 (Climate Action) requires continuous, high-frequency, and synoptic monitoring of surface water extent, volume variations, and inundation dynamics across transboundary river basins.

Traditional in situ hydrological monitoring techniques—including terrestrial streamflow gauging stations, river stage loggers, bathymetric sonar surveys, and manned airborne reconnaissance—are severely constrained by sparse geographic distribution, prohibitive capital and operational maintenance costs, data latency, and physical vulnerability during extreme weather events. In developing nations and remote transboundary wilderness regions, streamflow gauge networks are increasingly decommissioned due to budgetary constraints. Consequently, spaceborne satellite Earth Observation (EO) represents the only viable technology capable of providing synoptic, continuous, repeatable, and high-frequency surveillance of global surface water dynamics across transboundary river basins and remote wilderness areas [7], [8].

Ahmad Nawaz Zaheer is with BOYA International College, Jiangxi Institute of Technology, 115 Ziyang Avenue, Nanchang, 330022, Jiangxi, China (e-mail: alpha@jxut.edu.cn, caosuirong@jxut.edu.cn).

Muhammad Farhan is with the Department of Computer Science, COMSATS University Islamabad, Sahiwal Campus, Pakistan (e-mail: farhan@cuisahiwal.edu.pk; farhansajid@gmail.com).

The complete source code, trained graph policies, and standardized water resources benchmark datasets are publicly accessible at <https://github.com/farhansajid/RL-HydroFM>.

Fig. 1: Few-shot classification performance comparison (Top-1 Accuracy % vs. Number of Shots  $n \in \{1, 2, 4, 8, 16\}$ ) across four Earth observation water resources benchmarks: (a) EuroSAT-Water, (b) Sentinel-2 Water Bodies, (c) Sen12-Flood, and (d) RESISC45-Water. Curves and error bands denote mean and standard deviation over 5 independent random seeds. RL-HYDROFM+SAR (teal star) and RL-HYDROFM (red circle) consistently achieve superior accuracy across all shot regimes, with the most pronounced gains in the extreme low-shot regime (1-shot and 2-shot).

### A. Physical Foundations of Multi-Source Hydrological Remote Sensing

Spaceborne satellite remote sensing leverages distinct physical interactions across the electromagnetic spectrum to characterize terrestrial surface water:

1) *Optical Multi-Spectral Reflectance and Radiative Transfer*: Optical sensors, such as the European Space Agency's (ESA) Copernicus Sentinel-2 Multi-Spectral Instrument (MSI) and NASA/USGS Landsat 8/9 Operational Land Imager (OLI), measure reflected solar radiation across 13 spectral bands spanning visible (443–665 nm), red-edge (705–783 nm), near-infrared (NIR, 842 nm), and short-wave infrared (SWIR, 1610–2190 nm) wavelengths [7]. Pure liquid water exhibits strong absorption in the NIR and SWIR regimes, resulting in very low reflectance ( $< 2\%$ ), whereas green vegetation and dry soils exhibit high reflectance due to leaf cellular scattering and mineral composition.

Handcrafted spectral indices, such as the Normalized Difference Water Index ( $NDWI = \frac{\rho_{Green} - \rho_{NIR}}{\rho_{Green} + \rho_{NIR}}$ ) [9] and Modified NDWI ( $MNDWI = \frac{\rho_{Green} - \rho_{SWIR}}{\rho_{Green} + \rho_{SWIR}}$ ) [10], exploit this contrast. The top-of-atmosphere (TOA) radiance  $L_{TOA}(\lambda)$  observed by the satellite sensor is governed by the atmospheric radiative transfer equation:

$$L_{TOA}(\lambda) = L_{path}(\lambda) + T_v(\lambda) \cdot \frac{\rho_w(\lambda) E_d(0^+, \lambda)}{\pi(1 - s(\lambda)\rho_w(\lambda))}, \quad (1)$$

where  $L_{path}(\lambda)$  is atmospheric path radiance from Rayleigh and aerosol scattering,  $T_v(\lambda)$  is diffuse atmospheric upward transmittance,  $E_d(0^+, \lambda)$  is downwelling solar irradiance,  $s(\lambda)$  is the atmospheric spherical albedo, and  $\rho_w(\lambda)$  is water-leaving surface reflectance. Within the water column, downwelling irradiance  $E_d(z, \lambda)$  at depth  $z$  follows the Beer-Lambert attenuation law:

$$E_d(z, \lambda) = E_d(0^-, \lambda) \exp(-K_d(\lambda)z), \quad (2)$$

where  $K_d(\lambda) = a(\lambda) + b_b(\lambda)$  represents the diffuse attenuation coefficient, governed by total absorption  $a(\lambda)$  and backscattering  $b_b(\lambda)$  of pure water, suspended particulate matter (SPM),

and colored dissolved organic matter (CDOM) [2]. Under Gordon's bio-optical radiative model, subsurface remote sensing reflectance  $r_{rs}(\lambda)$  relates to inherent optical properties via:

$$r_{rs}(\lambda) = g_1 \frac{b_b(\lambda)}{a(\lambda) + b_b(\lambda)} + g_2 \left( \frac{b_b(\lambda)}{a(\lambda) + b_b(\lambda)} \right)^2, \quad (3)$$

where  $g_1 \approx 0.0949$  and  $g_2 \approx 0.0794$  are geometric expansion coefficients.

2) *Shallow-Water Bathymetry and Radiative Transfer Mechanics*: In optically shallow inland waters, braided river sandbars, and littoral wetlands, subsurface reflectance is jointly governed by water column volume scattering and benthic substrate albedo  $\rho_b(\lambda)$ . The exact semi-analytical shallow-water radiative transfer equation is formulated as:

$$r_{rs}(\lambda) = r_{rs}^{dp}(\lambda) \left( 1 - \exp(-[K_d(\lambda) + D_u K_u^C(\lambda)]z_b) \right) + \frac{\rho_b(\lambda)}{\pi} \exp(-[K_d(\lambda) + D_u K_u^B(\lambda)]z_b), \quad (4)$$

where  $r_{rs}^{dp}(\lambda)$  is the asymptotic optically deep water reflectance,  $z_b$  is the bathymetric water depth,  $D_u \approx 1.03(1 + 2.4 \frac{b_b}{a+b_b})^{0.5}$  is the optical path elongation factor, and  $K_u^C(\lambda), K_u^B(\lambda)$  are the upwelling attenuation coefficients for water column and bottom reflectance, respectively. Above the water surface, the water-leaving remote sensing reflectance  $R_{rs}(\lambda)$  observed by the satellite is related to subsurface  $r_{rs}(\lambda)$  across the refractive air-water interface via:

$$R_{rs}(\lambda) = \frac{\zeta r_{rs}(\lambda)}{1 - \Gamma r_{rs}(\lambda)}, \quad (5)$$

where  $\zeta \approx 0.52$  accounts for the internal refractive index mismatch ( $n_w \approx 1.334$ ) and Fresnel water-to-air transmittance, and  $\Gamma \approx 1.56$  represents the internal reflection factor. When water depth  $z_b < 1.5$  m, bright sandy substrates elevate NIR reflectance, causing static spectral indices to misclassify shallow waters as dry soil. Concurrently, suspended particulate matter absorbs blue light and scatters red-edge wavelengths, distorting optical index ratios.

3) *Microwave Synthetic Aperture Radar (SAR) Scattering Mechanics*: Active microwave radar systems, such as Sentinel-1 C-band (5.405 GHz,  $\lambda \approx 5.6$  cm), transmit coherent microwave pulses and record backscatter intensity ( $\sigma_{VV}^0, \sigma_{VH}^0$ ) [4], [5]. Because microwave radiation penetrates clouds, rain, and smoke day and night, SAR is the premier operational tool for flood surveillance during heavy storms.

The dielectric permittivity of liquid water at C-band frequencies is exceptionally high ( $\epsilon^* = \epsilon' - j\epsilon''$  with  $\epsilon' \approx 80$ ), compared to dry soil ( $\epsilon' \approx 4$ –6) and vegetation ( $\epsilon' \approx 10$ –20). According to the Fresnel reflection equations, calm open water acts as an electromagnetic specular mirror, directing incident microwave energy away from the radar antenna and resulting in extremely low backscatter ( $\sigma^0 \leq -18$  dB). Conversely, dry soil and dense vegetation produce diffuse volume scattering ( $\sigma^0 \approx -10$  dB), while inundated urban areas produce double-bounce corner reflections from vertical building walls and horizontal standing water ( $\sigma^0 \geq -3$  dB) [4]. Under the Sinclair scattering matrix formulation  $\mathbf{S} = \begin{bmatrix} S_{VV} & S_{VH} \\ S_{HV} & S_{HH} \end{bmatrix}$ , reciprocity enforces  $S_{VH} = S_{HV}$  in monostatic configurations. The target coherency matrix  $\mathbf{T}_3$  is defined as:

$$\mathbf{T}_3 = \frac{1}{2} \begin{bmatrix} \langle |S_{HH} + S_{VV}|^2 \rangle & \langle (S_{HH} + S_{VV})(S_{HH} - S_{VV})^* \rangle \\ \langle (S_{HH} - S_{VV})(S_{HH} + S_{VV})^* \rangle & \langle |S_{HH} - S_{VV}|^2 \rangle \\ 2\langle S_{HV}(S_{HH} + S_{VV})^* \rangle & 2\langle S_{HV}(S_{HH} - S_{VV})^* \rangle \end{bmatrix} \quad (6)$$

However, SAR imagery is corrupted by granular speckle noise, wind-induced capillary waves, and radar shadow/layover in mountainous terrain.

4) *Radar Altimetry and Wide-Swath Interferometry*: Specialized missions, such as the Surface Water and Ocean Topography (SWOT) satellite, employ Ka-band Radar Interferometers (KaRIn) with a  $B = 10$  m baseline to measure 2D surface water elevations  $h(x, y)$ , lake storage volumes, and river slopes via interferometric phase difference:

$$\Delta\Phi = \frac{2\pi B}{\lambda} \sin(\theta - \alpha), \quad h(x, y) = H - \rho \cos \theta, \quad (7)$$

where  $\theta$  is the incidence angle,  $\alpha$  is the baseline tilt angle,  $H$  is the satellite orbital altitude, and  $\rho$  is the slant range distance. The integration of optical, SAR, and altimetric observations provides unprecedented capabilities for hydrological surveillance across diverse geographic basins.

### B. The Emergence of Geospatial Foundation Models

To harness these massive multi-sensor archives without requiring millions of task-specific training labels, Earth observation artificial intelligence has recently transitioned toward *Geospatial Foundation Models* (GFM) [11]–[13]. Pre-trained on vast archives of satellite imagery using self-supervised learning (SSL) or contrastive vision-language pre-training (VLP) [14], foundation models learn rich representations of spatial, spectral, and semantic priors [15]–[18]. Foundation models such as GeoRSCLIP [11], RemoteCLIP [13], SkyCLIP [19], and DINOv3 [12] demonstrate remarkable zero-shot transfer capabilities by aligning satellite imagery and descriptive textual prompts in a joint embedding space.

### C. The Few-Shot Adaptation Challenge in Operational Hydrology

Despite their impressive representational capabilities, transferring geospatial foundation models to specialized water resources tasks encounters several fundamental operational and methodological bottlenecks:

#### 1) **Extreme Annotation Scarcity in Dynamic Disasters:**

In rapid-onset hydrological emergencies, ground-truth reference labels are virtually unavailable at the time of satellite acquisition. Rapid operational deployment requires foundation models to adapt effectively in the extreme *few-shot regime* (1-shot to 4-shot) from a handful of historical exemplars or user-provided geographic anchors. Inductive few-shot methods (e.g., Prototypical Networks [20], Linear Probing [21]) fail to model the target domain distribution accurately with such minimal support.

#### 2) **Heuristic Rigidity of Transductive Manifold Graph Construction:**

In operational remote sensing, satellite images are acquired in large contiguous spatial tiles. These tiles can be processed jointly as an unlabeled query set  $\mathcal{Q}$  using *transductive inference* [22]–[24]. Transductive Information Maximization (TIM++) and Locally Consistent TIM (LC-TIM) optimize class prototypes by maximizing mutual information between query features and predictions while enforcing consistency across a  $k$ -nearest-neighbor ( $\kappa$ -NN) graph. However, existing methods rely on rigid, handcrafted heuristics: a uniform static neighborhood size ( $\kappa = 5$ ) and constant regularizer weight ( $\lambda_{LC} = 0.3$ ) applied uniformly across all samples. In complex hydrological landscapes, thin braided river networks, shallow wetlands, and heterogeneous shorelines exhibit variable local manifold density. Static graphs cause *label contamination* by connecting isolated boundary samples to mismatched land-cover classes, while dense open-water clusters are constrained by artificially small  $\kappa$ .

#### 3) **Severe Atmospheric Cloud Degradation:**

Severe flood events and intense precipitation are almost invariably accompanied by heavy atmospheric cloud cover and cloud shadows. Optical sensors (Sentinel-2, GeoRSCLIP) suffer severe spectral attenuation and cloud obstruction under overcast skies, rendering optical-only foundation models ineffective. Conversely, active microwave radar (Sentinel-1 SAR) penetrates clouds effortlessly but is corrupted by speckle noise, dielectric roughness variations, and double-bounce scattering from flooded urban structures [4]. Existing multi-source fusion models enforce static, heuristic weighting between optical and SAR modalities, failing to adaptively re-weight sensors when optical visibility is degraded.

### D. Our Proposed Solution: RL-HYDROFM

To overcome these fundamental limitations, this paper introduces **RL-HYDROFM (Reinforcement-Learned Hydro Foundation Model Adaptation)**. RL-HYDROFM integrates Reinforcement Learning (RL) directly into the transductive

Fig. 2: Multi-dimensional radar evaluation comparing Zero-Shot, ProtoNet, Tip-Adapter, LP++, TransCLIP, TIM++, LC-TIM, and RL-HYDROFM+SAR across six key operational criteria: 1-Shot Accuracy, 16-Shot Accuracy, Macro-F1, Cloud Resilience, Uncertainty Calibration, and Boundary Sensitivity. RL-HYDROFM+SAR exhibits comprehensive superiority across all operational metrics.

inference loop of geospatial foundation models. We formulate the construction of the transductive neighborhood graph, the sample-specific regularization strength, and the multi-source optical-SAR sensor fusion as a unified Markov Decision Process (MDP). An Actor-Critic Graph Policy Network observes zero-shot predictive entropy, local topological density, and cross-modal concordance to dynamically assign:

- 1) Sample-wise neighborhood cardinalities  $\kappa_i \in \{1, 3, 5, 8, 12, 16\}$ ;
- 2) Confidence-calibrated local consistency regularization strengths  $\lambda_{LC,i} \in [0, 1]$ ;
- 3) Dynamic multi-modal sensor routing coefficients  $\beta_i = [\beta_{opt,i}, \beta_{sar,i}] \in \Delta^1$ .

Crucially, these policy-generated dynamic regularizers enter directly into a vectorized, closed-form Alternating Direction Method (ADM) solver. This design guarantees that no gradient updates are backpropagated into the frozen foundation model backbones (e.g., GeoRSCLIP and DINOv3), preserving massive computational efficiency and enabling sub-second inference on edge GPU hardware.

The primary contributions of this work are summarized as follows:

- **Novel Methodological Paradigm:** We propose RL-HYDROFM, the first framework to formulate transductive neighborhood graph construction and multi-source foundation model adaptation as a reinforcement learning optimization problem for Earth observation.
- **Adaptive Multi-Modal Sensor Routing:** We design an Actor-Critic policy that dynamically routes optical semantics and radar backscatter based on real-time atmospheric and topological uncertainty, providing unprecedented cloud-penetrating resilience for flood monitoring.
- **Vectorized Closed-Form ADM Solver:** We derive an exact, sample-adaptive  $q$ -update solver that seamlessly

incorporates policy actions with negligible computational latency.

- **Comprehensive Benchmarking on Water Resources:** We establish extensive experiments across four diverse Earth observation water benchmarks (EuroSAT-Water, Kaggle Sentinel-2 Water Bodies, Sen12-Flood, and RESISC45-Water) comparing 11 baseline methods, demonstrating that RL-HYDROFM achieves state-of-the-art accuracy, decisively outperforming inductive and transductive baselines in the low-shot regime.
- **Open-Source Codebase & Reproducibility:** The full PyTorch implementation, trained policy weights, and evaluation benchmark protocols are publicly accessible at <https://github.com/farhansajid/RL-HydroFM>.

### E. Operational Significance for Global Water Governance

Effective water governance in the era of planetary climate change necessitates transitioning from fragmented, retrospective hydrological reporting toward automated, forward-looking Earth observation analytics. The operational deployment of RL-HYDROFM provides water resource managers, disaster response authorities, and transboundary river basin commissions with an automated, zero-shot to few-shot analytical capability. By enabling rapid, reliable delineation of standing water bodies, ephemeral flood channels, and vulnerable agricultural zones without requiring weeks of localized field surveys, this framework directly bridges the critical gap between raw petabyte-scale satellite data downlinks and actionable geospatial intelligence.

The remainder of this article is structured as follows. Section II reviews related work. Section III details the problem setup and theoretical limitations of static graphs. Section IV presents the mathematical formulation of RL-HYDROFM and the closed-form ADM derivations. Section V details experimental datasets, baselines, and protocols. Section VI presents quantitative benchmarking and comparative analysis. Section VII provides in-depth ablation studies and computational efficiency profiles. Section VIII discusses hydrological implications and operational deployment. Section IX concludes the paper.

## II. RELATED WORK

### A. Geospatial Foundation Models in Remote Sensing

Pre-trained foundation models have revolutionized Earth observation by establishing general-purpose visual representations that transfer across diverse downstream tasks [11], [12], [15]. In contrast to traditional supervised deep neural networks trained on narrow, task-specific datasets, foundation models are trained on massive archives of satellite imagery using self-supervised learning (SSL) or contrastive vision-language pre-training (VLP) [14].

In vision-language modeling, RemoteCLIP [13], GeoRSCLIP [11], and SkyCLIP [19] align satellite multi-spectral imagery with descriptive domain-specific text captions derived from crowdsourced geospatial databases (e.g., OpenStreetMap) and automated vision-language bootstrapping. The fundamental contrastive objective

minimizes the symmetric InfoNCE loss across a mini-batch of  $B$  image-text pairs  $\{(\mathbf{x}_i, \mathbf{c}_i)\}_{i=1}^B$ :

$$\mathcal{L}_{\text{VLP}} = -\frac{1}{2B} \sum_{i=1}^B \left[ \log \frac{\exp(\mathbf{f}_i^\top \mathbf{t}_i / \tau_0)}{\sum_{j=1}^B \exp(\mathbf{f}_i^\top \mathbf{t}_j / \tau_0)} + \log \frac{\exp(\mathbf{t}_i^\top \mathbf{f}_i / \tau_0)}{\sum_{j=1}^B \exp(\mathbf{t}_i^\top \mathbf{f}_j / \tau_0)} \right], \quad (8)$$

where  $\mathbf{f}_i = \theta_{\text{opt}}(\mathbf{x}_i)$  and  $\mathbf{t}_i = \theta_{\text{ext}}(\mathbf{c}_i)$  denote normalized visual and textual embeddings, and  $\tau_0$  is a learnable temperature. These models enable zero-shot classification and zero-shot open-vocabulary retrieval by computing cosine similarity between satellite image embeddings and text prompt representations.

Concurrently, masked autoencoding architectures—such as SatMAE [15], Prithvi-100M/300M [16], Scale-MAE [17], and RingMo [25]—reconstruct masked spatial-spectral patches from multi-spectral Sentinel-2 and Landsat pixels, capturing deep geometric and physical dependencies. Furthermore, self-supervised vision transformers such as DINOv2 and DINOv3 [12] demonstrate exceptional feature granularity, dense spatial correspondence, and out-of-distribution robustness. In this work, we harness frozen GeoRSClip and DINOv3 representations, completely eliminating the prohibitive cost of full-parameter fine-tuning while exploiting their rich geospatial representations.

### B. Multi-Source Remote Sensing for Hydrological Surveillance

Surface water extraction and flood inundation mapping have historically relied on handcrafted multi-spectral indices, such as the Normalized Difference Water Index (NDWI) [9], Modified NDWI (MNDWI) [10], and Automated Water Extraction Index (AWEI) [1]. While optical spectral indices operate effectively under clear skies, they fail catastrophically in the presence of cloud cover, cloud shadows, and haze [2].

To achieve all-weather day-and-night surface water surveillance, Synthetic Aperture Radar (SAR) systems, such as Sentinel-1 C-band radar, emit microwave pulses and record backscatter intensity  $(\sigma_{\text{VV}}^0, \sigma_{\text{VH}}^0)$  [4], [5]. Calm open water acts as a specular reflector, scattering microwave energy away from the radar antenna and appearing as dark patches in SAR backscatter imagery. However, wind-induced surface waves, capillary roughness, urban double-bounce reflections, and speckle noise frequently cause severe classification ambiguity.

The Cloude-Pottier eigenvalue-eigenvector decomposition of the coherency matrix  $\mathbf{T}_3$  represents backscattering mechanisms via entropy  $H$ , anisotropy  $A$ , and mean alpha angle  $\bar{\alpha}$ :

$$\bar{\alpha} = \sum_{i=1}^3 P_i \alpha_i, \quad H = -\sum_{i=1}^3 P_i \log_3 P_i, \quad (9)$$

where  $P_i$  are normalized eigenvalues, distinguishing surface scattering ( $\bar{\alpha} \rightarrow 0^\circ$ ), double bounce ( $\bar{\alpha} \rightarrow 90^\circ$ ), and volume scattering ( $\bar{\alpha} \approx 45^\circ$ ). Recent multi-source data fusion frameworks [8], [26] demonstrate that combining complementary optical multi-spectral and microwave SAR observations

provides the most reliable foundation for water resources monitoring. However, previous fusion methods employ static, heuristic weighting that cannot adapt when one modality is degraded.

### C. Inductive vs. Transductive Few-Shot Adaptation

Few-shot learning aims to recognize novel target categories given only a tiny labeled support set  $\mathcal{S}$  [20], [27]–[29]. In inductive few-shot learning, the model adapts parameters solely based on the support set  $\mathcal{S}$  and evaluates query samples  $\mathbf{x} \in \mathcal{Q}$  independently. Inductive baselines include Prototypical Networks (ProtoNet) [20], Linear Probing (LP++) [21], and training-free key-value cache adapters such as Tip-Adapter [30].

In contrast, transductive few-shot learning processes the entire unlabeled query batch  $\mathcal{Q}$  jointly at inference time [22]–[24], [31]. In remote sensing, transductive learning is particularly practical because satellite data is acquired in large geographic tiles comprising thousands of contiguous pixels or patches. Transductive Information Maximization (TIM++) [23] maximizes the mutual information between query representations and predictions while penalizing divergence from zero-shot textual priors. Locally Consistent TIM (LC-TIM) [24] augments TIM++ with a local consistency regularizer across a  $k$ -nearest-neighbor graph. However, LC-TIM enforces a static graph topology ( $\kappa = 5$ ) and constant regularizer weight ( $\lambda_{\text{LC}} = 0.3$ ), leading to severe label bleeding across complex hydrological boundaries.

### D. Reinforcement Learning in Earth Observation

Reinforcement learning (RL) has emerged as a powerful paradigm for autonomous decision-making in remote sensing, including satellite constellation scheduling, agile Earth observation tasking, and autonomous UAV path planning [32]–[34]. The policy gradient theorem states that the gradient of expected trajectory reward  $J(\theta)$  is:

$$\nabla_{\theta} J(\theta) = \mathbb{E}_{\pi_{\theta}} [\nabla_{\theta} \log \pi_{\theta}(\mathbf{a} | \mathbf{s}) Q^{\pi_{\theta}}(\mathbf{s}, \mathbf{a})]. \quad (10)$$

In vision-language processing, RLPrompt [35] employs policy gradients to optimize discrete textual prompts without backpropagation into the language model. Proximal Policy Optimization (PPO) [33] provides stable policy gradient optimization with clipped surrogate objectives. Unlike prior works that apply RL to full model parameter fine-tuning, RL-HYDROFM employs RL as a lightweight, plug-and-play meta-controller for dynamic manifold graph construction and multi-source sensor gating.

### E. Synthesis and Distinctions of the Proposed Approach

While previous literature has addressed either transductive adaptation or multi-modal fusion in isolation, RL-HYDROFM is the first framework to synthesize both mechanisms under an adaptive reinforcement-learned control policy. By treating the construction of the transductive manifold graph as a discrete Markov Decision Process, our approach eliminates heuristic hyperparameter tuning and guarantees mathematically bounded convergence over frozen foundation embeddings.

### III. PROBLEM FORMULATION & THEORETICAL FOUNDATIONS

#### A. Mathematical Setup & Embeddings

Let  $\theta_{\text{opt}}(\cdot)$  denote the visual encoder of a frozen optical geospatial foundation model (e.g., GeoRSCLIP ViT-B/32),  $\theta_{\text{text}}(\cdot)$  its text encoder, and  $\theta_{\text{sar}}(\cdot)$  a supplemental structural/SAR vision transformer (e.g., Sentinel-1 SAR encoder or DINOv3 SAT-493M). For an input satellite image  $\mathbf{x}_i$ , the  $\ell_2$ -normalized optical and SAR embeddings are:

$$\mathbf{f}_i = \frac{\theta_{\text{opt}}(\mathbf{x}_i)}{\|\theta_{\text{opt}}(\mathbf{x}_i)\|_2} \in \mathbb{R}^{d_1}, \quad \mathbf{g}_i = \frac{\theta_{\text{sar}}(\mathbf{x}_i)}{\|\theta_{\text{sar}}(\mathbf{x}_i)\|_2} \in \mathbb{R}^{d_2}. \quad (11)$$

For a set of  $K$  target water and land-cover classes, let  $\mathbf{c}_k$  denote the domain-specific textual prompt describing class  $k \in \{1, \dots, K\}$  (e.g., “a Sentinel-2 satellite photo of a river channel”). The normalized textual prototype is:

$$\mathbf{t}_k = \frac{\theta_{\text{text}}(\mathbf{c}_k)}{\|\theta_{\text{text}}(\mathbf{c}_k)\|_2} \in \mathbb{R}^{d_1}. \quad (12)$$

The zero-shot prior  $\hat{\mathbf{y}}_i = (\hat{y}_{i1}, \dots, \hat{y}_{iK}) \in \Delta^{K-1}$  is given by the cosine-similarity Softmax:

$$\hat{y}_{ik} = \frac{\exp(\eta \mathbf{f}_i^\top \mathbf{t}_k)}{\sum_{j=1}^K \exp(\eta \mathbf{f}_i^\top \mathbf{t}_j)}, \quad (13)$$

where  $\eta = 100$  is a fixed inverse temperature scaling factor.

We consider a few-shot transductive setup with a small labeled support set  $\mathcal{S} = \{(\mathbf{x}_i, y_{ik})\}_{i \in \mathcal{S}}$  containing  $n \in \{1, 2, 4, 8, 16\}$  samples per class ( $|\mathcal{S}| = N_s = nK$ ), and an unlabeled query set  $\mathcal{Q} = \{\mathbf{x}_i\}_{i \in \mathcal{Q}}$  comprising  $|\mathcal{Q}| = N_q$  tiles. A soft prototype classifier matrix  $\mathbf{W} = [\mathbf{w}_1, \dots, \mathbf{w}_K] \in \mathbb{R}^{d_1 \times K}$  generates query posterior class probabilities:

$$p_{ik} = \frac{\exp(-\frac{\tau}{2} \|\mathbf{f}_i - \mathbf{w}_k\|^2)}{\sum_{j=1}^K \exp(-\frac{\tau}{2} \|\mathbf{f}_i - \mathbf{w}_j\|^2)}, \quad (14)$$

where  $\tau = 120$  is the metric scaling temperature.

#### B. Base Transductive Information Maximization

The foundational transductive objective optimizes prototype matrix  $\mathbf{W}$  by minimizing a composite loss over support supervision, query mutual information, and zero-shot text alignment:

$$\min_{\mathbf{W}} \lambda \text{CE}(\mathbf{W}; \mathcal{S}) - \hat{\mathcal{I}}_\alpha(X_{\mathcal{Q}}; Y_{\mathcal{Q}}) + \gamma \mathcal{D}_{\text{KL}}(\mathbf{p} \parallel \hat{\mathbf{y}}), \quad (15)$$

where:

$$\text{CE}(\mathbf{W}; \mathcal{S}) = -\frac{1}{|\mathcal{S}|} \sum_{i \in \mathcal{S}} \sum_{k=1}^K y_{ik} \log p_{ik}, \quad (16)$$

and  $\hat{\mathcal{I}}_\alpha(X_{\mathcal{Q}}; Y_{\mathcal{Q}}) = \alpha \hat{\mathcal{H}}(Y_{\mathcal{Q}}) - \hat{\mathcal{H}}(Y_{\mathcal{Q}} | X_{\mathcal{Q}})$  represents the  $\alpha$ -generalized empirical mutual information. The marginal entropy  $\hat{\mathcal{H}}(Y_{\mathcal{Q}}) = -\sum_k \bar{p}_k \log \bar{p}_k$  (where  $\bar{p}_k = \frac{1}{N_q} \sum_i p_{ik}$ ) prevents majority-class collapse, while the conditional entropy  $\hat{\mathcal{H}}(Y_{\mathcal{Q}} | X_{\mathcal{Q}}) = -\frac{1}{N_q} \sum_i \sum_k p_{ik} \log p_{ik}$  drives confident, decisive cluster assignments.

#### C. Theoretical Failure Modes of Static Neighborhood Graphs

Locally consistent transduction [24] penalizes divergence between query posteriors  $\mathbf{p}_i$  and the average prediction of their neighbors  $\bar{\mathbf{p}}_i = \frac{1}{\kappa} \sum_{j \in \mathcal{N}_i(\kappa)} \mathbf{p}_j$ . Here, we formally analyze why enforcing a uniform static  $\kappa = 5$  across all satellite tiles leads to catastrophic label contamination:

**Definition 1** (Manifold Boundary Distance). Let  $\mathcal{M}_k \subset \mathbb{R}^d$  denote the continuous sub-manifold corresponding to hydrological class  $k$ , and let  $\partial \mathcal{M}_{k,l}$  denote the decision boundary separating class  $k$  from adjacent class  $l$ . For any query feature  $\mathbf{f}_i \in \mathcal{M}_k$ , the geometric boundary margin is  $\delta_i = \inf_{\mathbf{z} \in \partial \mathcal{M}_{k,l}} \|\mathbf{f}_i - \mathbf{z}\|_2$ .

**Lemma 1** (Cross-Manifold Edge Contamination). Let the local feature density around boundary point  $\mathbf{f}_i \in \mathcal{M}_k$  be  $\rho_k(\mathbf{f}_i)$ . For a static neighborhood size  $\kappa$ , the radius of the  $\kappa$ -nearest-neighbor ball is  $r_i(\kappa) = \left(\frac{\kappa}{N_q V_d \rho_k(\mathbf{f}_i)}\right)^{1/d}$ , where  $V_d$  is the volume of the unit ball in  $\mathbb{R}^d$ . If  $r_i(\kappa) > \delta_i$ , the neighborhood  $\mathcal{N}_i(\kappa)$  contains at least one cross-class edge:

$$\exists j \in \mathcal{N}_i(\kappa) \text{ such that } \mathbf{f}_j \in \mathcal{M}_l \quad (l \neq k). \quad (17)$$

**Theorem 1** (Label Bias Propagation Bound). Let  $\mathbf{e}_k \in \{0, 1\}^K$  denote the true one-hot class vector for  $\mathbf{f}_i \in \mathcal{M}_k$ . Under a static  $\kappa$ -NN graph, the label bias introduced into the local consistency regularizer for boundary sample  $\mathbf{f}_i$  satisfies:

$$\|\bar{\mathbf{p}}_i - \mathbf{e}_k\|_1 \geq \frac{1}{\kappa} \sum_{j \in \mathcal{N}_i(\kappa)} \mathbb{I}(\mathbf{f}_j \notin \mathcal{M}_k) \cdot (1 - p_{jk}). \quad (18)$$

As  $\kappa$  increases in low-density boundary zones, the regularizer enforces consensus with mismatched land-cover classes, creating systematic error propagation.

*Proof.* By definition of the consensus vector,  $\bar{\mathbf{p}}_i = \frac{1}{\kappa} \sum_{j \in \mathcal{N}_i(\kappa)} \mathbf{p}_j$ . Decomposing the sum into intra-manifold neighbors  $\mathcal{N}_i^{\text{in}} = \{j \in \mathcal{N}_i \mid \mathbf{f}_j \in \mathcal{M}_k\}$  and cross-manifold neighbors  $\mathcal{N}_i^{\text{cross}} = \{j \in \mathcal{N}_i \mid \mathbf{f}_j \notin \mathcal{M}_k\}$ :

$$\bar{p}_{ik} = \frac{1}{\kappa} \sum_{j \in \mathcal{N}_i^{\text{in}}} p_{jk} + \frac{1}{\kappa} \sum_{j \in \mathcal{N}_i^{\text{cross}}} p_{jk} \leq \frac{|\mathcal{N}_i^{\text{in}}|}{\kappa} + \frac{1}{\kappa} \sum_{j \in \mathcal{N}_i^{\text{cross}}} p_{jk}. \quad (19)$$

Since  $1 - \bar{p}_{ik} \geq \frac{1}{\kappa} \sum_{j \in \mathcal{N}_i^{\text{cross}}} (1 - p_{jk})$ , applying the  $\ell_1$  norm definition yields the stated lower bound.  $\square$

**Corollary 1** (Optimal Dynamic Regularization). For ambiguous boundary samples where zero-shot predictive entropy is high ( $\mathcal{H}_i \rightarrow 1$ ) and margin is small ( $\Delta m_i \rightarrow 0$ ), setting  $\kappa_i = 1$  and  $\lambda_{LC,i} \rightarrow 0$  strictly eliminates cross-manifold label contamination. Conversely, for interior samples with  $\delta_i \gg r_i$ , expanding  $\kappa_i \geq 12$  maximizes transductive manifold smoothing without risk of contamination.

**Theorem 2** (Monotonic Convergence of Vectorized ADM Update). Let  $\mathcal{F}(\mathbf{Q}, \mathbf{W})$  denote the augmented transductive Lagrangian defined in Eq. (26). Under the alternating minimization scheme where  $\mathbf{Q}^{(t+1)} = \arg \min_{\mathbf{Q} \in \Delta} \mathcal{L}(\mathbf{Q}, \mathbf{W}^{(t)})$  and  $\mathbf{W}^{(t+1)} = \arg \min_{\mathbf{W}} \mathcal{L}(\mathbf{Q}^{(t+1)}, \mathbf{W})$ , the sequence

$\{\mathcal{F}(\mathbf{Q}^{(t)}, \mathbf{W}^{(t)})\}_{t=0}^{\infty}$  is monotonically non-increasing and converges to a local stationary point:

$$\mathcal{F}(\mathbf{Q}^{(t+1)}, \mathbf{W}^{(t+1)}) \leq \mathcal{F}(\mathbf{Q}^{(t+1)}, \mathbf{W}^{(t)}) \leq \mathcal{F}(\mathbf{Q}^{(t)}, \mathbf{W}^{(t)}). \quad (20)$$

*Proof.* Because the  $q$ -update is the unique closed-form minimizer of the convex subproblem  $\min_{\mathbf{Q} \in \Delta} \mathcal{L}(\mathbf{Q}, \mathbf{W}^{(t)})$  derived via KKT stationarity in Eq. (28),  $\mathcal{F}(\mathbf{Q}^{(t+1)}, \mathbf{W}^{(t)}) \leq \mathcal{F}(\mathbf{Q}^{(t)}, \mathbf{W}^{(t)})$ . Similarly, the centroid update in Eq. (29) minimizes the quadratic support and query alignment terms with respect to prototype vectors  $\mathbf{W}$ . Since  $\mathcal{F}$  is bounded below by zero (entropies and KL divergences are non-negative), the sequence converges monotonically by the Monotone Convergence Theorem.  $\square$

#### D. Geometric Analysis of Feature Manifold Curvature

To further elucidate the geometry of multi-source Earth observation features, let  $\mathcal{M} = \bigcup_{k=1}^K \mathcal{M}_k$  denote the Riemannian manifold embedded in Euclidean space  $\mathbb{R}^d$ . The Riemann curvature tensor  $R(X, Y)Z = \nabla_X \nabla_Y Z - \nabla_Y \nabla_X Z - \nabla_{[X, Y]} Z$  measures the non-flatness of the underlying geospatial representation space. In regions of high intrinsic curvature, such as convoluted shoreline boundaries and fractured urban terrain, standard Euclidean distance metrics severely distort geodesic relationships. By learning dynamic neighborhood bounds  $\kappa_i$  and multi-modal metric routing  $\beta_i$ , RL-HYDROFM effectively adapts to local Riemannian curvature, ensuring that graph diffusion occurs exclusively along the true data manifold rather than cutting across empty feature space.

### IV. THE PROPOSED RL-HYDROFM FRAMEWORK

#### A. Reinforcement-Learned Dynamic Graph Formulation

Motivated by Theorem 1 and Corollary 1, we formulate transductive graph construction and multi-source adaptation as a Markov Decision Process (MDP)  $(\mathcal{S}_{\text{env}}, \mathcal{A}, \mathcal{P}, \mathcal{R})$ :

1) **14-Dimensional Diagnostic State Representation:** For each query satellite tile  $i \in \mathcal{Q}$ , we construct a comprehensive 14-dimensional diagnostic state vector  $\mathbf{s}_i \in \mathbb{R}^{14}$ :

$$\mathbf{s}_i = [\bar{\mathcal{H}}_i, \Delta m_i, \hat{y}_{i,(1)}, \mu_{\text{sim},i}, \sigma_{\text{sim},i}, s_{\text{max},i}, s_{\text{min},i}, \Delta s_i, d_{\text{proto},i}, \mathbf{c}_{\text{cross},i}], \quad (21)$$

where each component captures a specific aspect of local topology and uncertainty:

- $\bar{\mathcal{H}}_i = -\sum_{k=1}^K \hat{y}_{ik} \log \hat{y}_{ik} / \log(K) \in [0, 1]$  is the normalized zero-shot predictive entropy.
- $\Delta m_i = \hat{y}_{i,(1)} - \hat{y}_{i,(2)} \in [0, 1]$  is the top-1 vs. top-2 probability margin.
- $\hat{y}_{i,(1)} \in [0, 1]$  is the maximum zero-shot confidence score.
- $[\mu_{\text{sim},i}, \sigma_{\text{sim},i}, s_{\text{max},i}, s_{\text{min},i}, \Delta s_i]$  capture local cosine similarity statistics among candidate neighbors.
- $d_{\text{proto},i} = [\max_k \mathbf{f}_i^\top \mathbf{w}_k, \text{gap}]$  measures geometric proximity to current support prototypes.
- $\mathbf{c}_{\text{cross},i} \in \mathbb{R}^4$  captures cross-modal alignment, rank correlation, and cosine similarity between optical and SAR feature spaces.

Fig. 3: Multi-modal robustness evaluation under progressive cloud attenuation (0% clear sky to 80% heavy overcast) on the Sen12-Flood benchmark. While Optical-only classification collapses by over 23%, RL-HYDROFM+SAR dynamically gates radar backscatter to maintain high accuracy ( $> 86\%$ ).

2) **Multi-Head Actor-Critic Policy Network:** The policy network  $\pi_\theta(\mathbf{a}_i|\mathbf{s}_i)$  processes state vector  $\mathbf{s}_i$  through a shared trunk comprising LayerNorm and two linear layers (hidden dimension 128) with GELU activations and Dropout (0.1). The trunk feeds four specialized output heads:

- 1) **Dynamic Cardinality Head ( $\kappa_i$ ):** Softmax categorical head outputting probabilities over discrete candidate neighborhood sizes  $\mathcal{K} = \{1, 3, 5, 8, 12, 16\}$ .
- 2) **Multi-Modal Sensor Routing Head ( $\beta_i$ ):** Softmax head predicting optical vs. SAR gating weights  $\beta_i = [\beta_{\text{opt},i}, \beta_{\text{sar},i}] \in \Delta^1$ .
- 3) **Sample-Adaptive Exponent Head ( $\lambda_{\text{LC},i}$ ):** Sigmoid head predicting local consistency regularizer strength  $\lambda_{\text{LC},i} \in [0, 1]$ .
- 4) **State-Value Critic Head ( $V_\phi$ ):** Linear regression head estimating scalar state value  $V_\phi(\mathbf{s}_i)$  for Generalized Advantage Estimation.

3) **Multi-Objective Transductive Reward Function:** The policy network is optimized to maximize a composite reward function balancing supervised validation performance, mutual information, and neighborhood consensus:

$$R(\mathbf{a}) = R_{\text{val\_acc}} + 0.15 \hat{\mathcal{I}}_\alpha(X_{\mathcal{Q}}; Y_{\mathcal{Q}}) + \omega_{\text{cons}} R_{\text{consensus}} - \omega_{\text{ent}} \hat{\mathcal{H}}(Y_{\mathcal{Q}}|X_{\mathcal{Q}}), \quad (22)$$

where  $R_{\text{consensus}} = \frac{1}{N_q} \sum_{i=1}^{N_q} \frac{1}{\kappa_i} \sum_{j \in \mathcal{N}_i} \mathbf{p}_i^\top \mathbf{p}_j$  measures prediction consensus among dynamically connected neighbors.

#### B. Vectorized Closed-Form ADM Optimization

Given policy actions  $(\kappa_i, \beta_i, \lambda_{\text{LC},i})$  for all query samples  $i \in \mathcal{Q}$ , the dynamic multi-modal affinity between query samples  $i$  and  $j$  is computed as:

$$a_{ij} = \beta_{\text{opt},i} \cdot \left( \frac{\mathbf{f}_i^\top \mathbf{f}_j + 1}{2} \right) + \beta_{\text{sar},i} \cdot \left( \frac{\mathbf{g}_i^\top \mathbf{g}_j + 1}{2} \right). \quad (23)$$

Let  $\mathcal{N}_i(\kappa_i, \beta_i)$  denote the top- $\kappa_i$  neighbors under affinity  $a_{ij}$ . The neighborhood consensus is:

$$\bar{\mathbf{p}}_i = \frac{1}{\kappa_i} \sum_{j \in \mathcal{N}_i(\kappa_i, \beta_i)} \mathbf{p}_j. \quad (24)$$

TABLE I: Comprehensive Summary of Earth Observation Water Resources &amp; Remote Sensing Few-Shot Benchmark Datasets.

| Benchmark Dataset       | Sensor Constellation        | Modality Type             | Spatial Resolution | Image Dimensions | # Classes | Evaluated Hydrological Categories                        |
|-------------------------|-----------------------------|---------------------------|--------------------|------------------|-----------|----------------------------------------------------------|
| EuroSAT-Water [7]       | Sentinel-2 MSI              | Multi-Spectral (13 Bands) | 10 m / 20 m        | 64 × 64          | 5         | River, Sea/Lake, Permanent Crop, Pasture, Herbaceous     |
| Sentinel-2 Water Bodies | Sentinel-2 MSI              | Optical Multi-Spectral    | 10 m               | 256 × 256        | 4         | Open Water, Turbid Water, Wetland, Dry Land              |
| Sen12-Flood [5]         | Sentinel-1 SAR + Sentinel-2 | Multi-Modal Optical + SAR | 10 m               | 256 × 256        | 3         | Flooded Inundation, Permanent Water, Non-Flooded Terrain |
| RESISC45-Water [36]     | Aerial VHR Orthoimagery     | RGB Optical               | 0.2 m – 30 m       | 256 × 256        | 7         | Lake, River, Wetland, Sea Ice, Harbor, Beach, Island     |

Our unified objective augments the transductive problem with sample-adaptive consistency:

$$\min_{\mathbf{W}} \lambda \text{CE}(\mathbf{W}; \mathcal{S}) - \hat{\mathcal{I}}_{\alpha}(X_{\mathcal{Q}}; Y_{\mathcal{Q}}) + \gamma \mathcal{D}_{\text{KL}}(\mathbf{p} \parallel \hat{\mathbf{y}}) + \frac{1}{|\mathcal{Q}|} \sum_{i \in \mathcal{Q}} \lambda_{\text{LC},i} \mathcal{D}_{\text{KL}}(\mathbf{p}_i \parallel \bar{\mathbf{p}}_i). \quad (25)$$

**Derivation of Closed-Form  $q$ -Update:** We introduce auxiliary assignment variables  $\mathbf{Q} = [q_{ik}] \in \mathbb{R}^{N_q \times K}$  constrained to the probability simplex  $\sum_k q_{ik} = 1$ . The Lagrangian of Eq. (25) with respect to  $q_{ik}$  is:

$$\mathcal{L}(\mathbf{Q}, \mu) = \sum_{i=1}^{N_q} \sum_{k=1}^K q_{ik} \left[ - (1 + \alpha) \log p_{ik} - \gamma \log \hat{y}_{ik} - \lambda_{\text{LC},i} \log \bar{p}_{ik} + \log q_{ik} \right] + \sum_{i=1}^{N_q} \mu_i \left( \sum_{k=1}^K q_{ik} - 1 \right). \quad (26)$$

Setting  $\frac{\partial \mathcal{L}}{\partial q_{ik}} = 0$  yields:

$$\log q_{ik} + 1 - (1 + \alpha) \log p_{ik} - \gamma \log \hat{y}_{ik} - \lambda_{\text{LC},i} \log \bar{p}_{ik} + \mu_i = 0. \quad (27)$$

Exponentiating both sides and normalizing over classes  $k \in \{1, \dots, K\}$  gives the exact closed-form update:

$$q_{ik}^{(t+1)} = \frac{(p_{ik}^{(t)})^{1+\alpha} \cdot \hat{y}_{ik}^{\gamma} \cdot (\bar{p}_{ik}^{(t)})^{\lambda_{\text{LC},i}}}{\sum_{k'=1}^K (p_{ik'}^{(t)})^{1+\alpha} \cdot \hat{y}_{ik'}^{\gamma} \cdot (\bar{p}_{ik'}^{(t)})^{\lambda_{\text{LC},i}}}. \quad (28)$$

**Prototype Matrix Update:** Using assignment matrix  $\mathbf{Q}$ , prototype column vectors  $\mathbf{w}_k$  are updated via closed-form weighted centroids:

$$\mathbf{w}_k^{(t+1)} = (1 - \alpha) \mathbf{w}_k^{(t)} + \alpha \frac{\frac{\lambda}{1+\lambda_2} \sum_{i \in \mathcal{S}} y_{ik} \mathbf{f}_i + \frac{N_{\mathcal{S}}}{N_q} \sum_{j \in \mathcal{Q}} q_{jk} \mathbf{f}_j}{\frac{\lambda}{1+\lambda_2} \sum_{i \in \mathcal{S}} y_{ik} + \frac{N_{\mathcal{S}}}{N_q} \sum_{j \in \mathcal{Q}} q_{jk}}. \quad (29)$$

### C. Algorithmic Complexity and Parallel Execution Guarantees

The computational complexity of Algorithm 1 scales linearly with the number of query samples  $N_q$ . Specifically, state extraction requires  $\mathcal{O}(N_q d_1 + N_q \kappa_{\text{cand}})$ , policy forward evaluation requires  $\mathcal{O}(N_q d_{\text{hid}})$ , and the vectorized ADM solver executes in  $\mathcal{O}(TN_q K + TN_q \kappa_{\text{max}})$  FLOPs. Because the entire inference routine consists of dense matrix-tensor multiplications implemented in native CUDA kernels, RL-HYDROFM avoids Python interpreter overhead and achieves deterministic execution latency on embedded tensor cores.

### Algorithm 1 RL-HydroFM Policy Training & Transductive Adaptation

**Require:** Support set  $(\mathbf{F}_{\mathcal{S}}, \mathbf{Y}_{\mathcal{S}})$ , Query set  $(\mathbf{F}_{\mathcal{Q}}, \mathbf{G}_{\mathcal{Q}})$ , text weights  $\mathbf{W}_{\text{text}}$ , policy  $\pi_{\theta}$ , value net  $V_{\phi}$ , max ADM iterations  $T = 150$ .

- 1: **// Step 1: Feature Representation and State Extraction**
- 2: Extract 14-dim state tensor  $\mathbf{S} \in \mathbb{R}^{N_q \times 14}$  using Eq. (21).
- 3: **// Step 2: Policy Decision Execution**
- 4: Sample actions  $\kappa, \mathbf{B}, \lambda_{\text{LC}} \sim \pi_{\theta}(\mathbf{S})$ .
- 5: Construct dynamic multi-modal affinity matrix  $\mathbf{A} \in \mathbb{R}^{N_q \times N_q}$  via Eq. (23).
- 6: Build variable-neighborhood index tensor  $\mathbf{K}_{\text{idx}} \in \mathbb{R}^{N_q \times 16}$  where row  $i$  stores the indices of top- $\kappa_i$  neighbors and zero-masks unused slots.
- 7: **// Step 3: Vectorized Closed-Form ADM Transduction**
- 8: Initialize  $\mathbf{W}^{(0)}$  via support centroids and zero-shot text prototypes.
- 9: **for** iteration  $t = 0$  to  $T - 1$  **do**
- 10:   Compute posterior probability matrix  $\mathbf{P}^{(t)}$  via Eq. (14).
- 11:   Compute dynamic consensus  $\bar{\mathbf{P}}^{(t)}$  via Eq. (24).
- 12:   Update assignments  $\mathbf{Q}^{(t+1)}$  in closed form via Eq. (28).
- 13:   Update prototype matrix  $\mathbf{W}^{(t+1)}$  via Eq. (29).
- 14: **end for**
- 15: **// Step 4: Policy Gradient Optimization (PPO)**
- 16: Compute multi-objective reward  $R(\mathbf{a})$  via Eq. (22).
- 17: Compute advantage  $\hat{A}_i = R(\mathbf{a}) - V_{\phi}(\mathbf{s}_i)$ .
- 18: Update policy parameters  $\theta \leftarrow \theta + \eta_{\text{pg}} \nabla_{\theta} \log \pi_{\theta}(\mathbf{a} | \mathbf{s}) \hat{A}$ .
- 19: Update critic parameters  $\phi \leftarrow \phi - \eta_{\text{critic}} \nabla_{\phi} (V_{\phi}(\mathbf{s}) - R(\mathbf{a}))^2$ .
- 20: **Return** Final posterior predictions  $\mathbf{P}^{(T)}$ .

*1) PPO Policy Optimization and Value Function Mechanics:* During meta-training, the Actor-Critic policy network parameters  $\theta$  and critic parameters  $\phi$  are jointly updated via the Proximal Policy Optimization (PPO) clipped surrogate loss:

$$\mathcal{L}_{\text{PPO}}(\theta) = \mathbb{E}_t \left[ \min \left( r_t(\theta) \hat{A}_t, \text{clip}(r_t(\theta), 1 - \epsilon_{\text{clip}}, 1 + \epsilon_{\text{clip}}) \hat{A}_t \right) \right], \quad (30)$$

where  $r_t(\theta) = \frac{\pi_{\theta}(\mathbf{a}_t | \mathbf{s}_t)}{\pi_{\theta_{\text{old}}}(\mathbf{a}_t | \mathbf{s}_t)}$  is the probability ratio,  $\epsilon_{\text{clip}} = 0.2$  is the clipping parameter, and  $\hat{A}_t$  is the Generalized Advantage Estimator (GAE) with discount  $\gamma_{\text{rl}} = 0.99$  and trace decay  $\lambda_{\text{gae}} = 0.95$ :

$$\hat{A}_t = \sum_{l=0}^{\infty} (\gamma_{\text{rl}} \lambda_{\text{gae}})^l \delta_{t+l}^V, \quad \delta_t^V = R_t + \gamma_{\text{rl}} V_{\phi}(\mathbf{s}_{t+1}) - V_{\phi}(\mathbf{s}_t). \quad (31)$$

The critic network minimizes the squared Bellman regression loss  $\mathcal{L}_{\text{critic}}(\phi) = \frac{1}{2} \mathbb{E}_t [(V_{\phi}(\mathbf{s}_t) - R_t)^2]$ , while an entropy bonus  $\mathcal{S}[\pi_{\theta}](\mathbf{s}_t) = - \sum_a \pi_{\theta}(a | \mathbf{s}_t) \log \pi_{\theta}(a | \mathbf{s}_t)$  is added to

prevent premature policy collapse to deterministic sub-optimal actions.

## V. EXPERIMENTAL SETUP & BENCHMARKS

### A. Benchmark Datasets & Radiometric Calibration

As summarized in Table I, we evaluate RL-HYDROFM across four Earth observation water resources benchmarks:

- 1) **EuroSAT-Water [7]:** Multi-spectral Sentinel-2 benchmark containing 13 spectral bands covering 5 target hydrological and land-cover categories: *River*, *SeaLake*, *PermanentCrop*, *Pasture*, and *HerbaceousVegetation*. Images are calibrated to Top-Of-Atmosphere (TOA) Level-1C reflectances at 10–60 m spatial resolution.
- 2) **Sentinel-2 Water Bodies:** High-resolution multi-spectral dataset curated for surface water identification, comprising 4 classes: *Open Water*, *Turbid Water*, *Wetland*, and *Dry Land*.
- 3) **Sen12-Flood [5]:** Dedicated multi-sensor flood disaster dataset containing paired Sentinel-1 SAR (dual-polarization VV and VH backscatter intensity  $\sigma^0$  in decibels) and Sentinel-2 optical multi-spectral scenes across 3 disaster categories: *Flooded Inundation*, *Permanent Water*, and *Non-Flooded Terrain*. SAR backscatter is speckle-filtered via Refined Lee filtering and radiometrically calibrated.
- 4) **RESISC45-Water [36]:** High-resolution aerial optical remote sensing benchmark comprising 7 fine-grained hydrological classes: *lake*, *river*, *wetland*, *sea ice*, *harbor*, *beach*, and *island*.

### B. Compared Baselines

We compare RL-HYDROFM against ten representative baselines spanning inductive, training-free, and transductive paradigms:

- **Zero-Shot:** GeoRSCLIP zero-shot inference with hydrological prompt templates.
- **ProtoNet [20]:** Classical metric few-shot prototypical nearest-centroid classifier.
- **LP++ [21]:** State-of-the-art inductive linear probe with learnable zero-shot calibration.
- **Tip-Adapter [30]:** Non-parametric training-free key-value cache adapter for vision-language models.
- **LaplacianShot [37]:** Transductive graph Laplacian smoothing with fixed-point diffusion.
- **TransCLIP [31]:** Gaussian-mixture transductive expectation-maximization baseline.
- **TIM++ [23]:** Mutual information transductive adaptation over frozen embeddings.
- **LC-TIM [24]:** Locally consistent TIM with static  $\kappa = 5$ ,  $\lambda_{LC} = 0.3$ .
- **LC-TIM+SAR:** Static optical-SAR multiplicative fusion baseline.
- **RL-HYDROFM (Ours):** Policy-driven dynamic graph adaptation on optical VLM.
- **RL-HYDROFM+SAR (Ours):** Multi-source optical + radar dynamic routing.

### C. Evaluation Metrics

Performance is evaluated across five standard metrics:

- 1) **Top-1 Accuracy (%)**: Proportion of correctly classified query tiles.
- 2) **Macro-F1 Score (%)**: Unweighted average of per-class F1-scores,  $\text{Macro-F1} = \frac{1}{K} \sum_{k=1}^K \frac{2P_k R_k}{P_k + R_k}$ , measuring balance across rare disaster water and majority dry terrain.
- 3) **Precision ( $P_k$ ) & Recall ( $R_k$ )**: Class-specific true positive fidelity and coverage.
- 4) **Expected Calibration Error (ECE)**: Difference between predictive confidence and empirical accuracy across 10 probability bins.
- 5) **GPU Runtime Latency (ms)**: Wall-clock execution time per query batch on an NVIDIA RTX GPU.

### D. Implementation Details & Prompt Dictionaries

All experiments run on PyTorch 2.1 with CUDA 12.1. Feature extraction uses frozen GeoRSCLIP ViT-B/32 ( $d_1 = 512$ ) and DINOv3 SAT-493M ( $d_2 = 768$ ). The policy network is optimized with Adam ( $\eta_{pg} = 3 \times 10^{-4}$ ,  $\eta_{critic} = 1 \times 10^{-3}$ ) for 300 epochs with PPO clip parameter  $\epsilon_{clip} = 0.2$ . ADM iterations use temperature  $\tau = 120$ ,  $\lambda = 1.0$ ,  $\lambda_2 = 0.01$ ,  $\gamma = 0.05$ ,  $\alpha = 0.1$ .

### E. Multi-Sensor Spatial and Temporal Alignment

Because Sentinel-2 MSI multi-spectral bands vary in ground sampling distance (10 m for visible and NIR, 20 m for red-edge and SWIR, and 60 m for atmospheric bands), all multi-spectral bands are resampled to a uniform 10 m grid using bicubic spline interpolation prior to foundation model encoding. For multi-modal Sen12-Flood tiles, Sentinel-1 C-band SAR Level-1 Ground Range Detected (GRD) products at 10 m pixel spacing are coregistered to the Sentinel-2 optical grid using the European Space Agency SNAP toolbox with Copernicus 30 m Global Digital Elevation Model (DEM) range-Doppler terrain correction. Radiometric calibration applies thermal noise removal and converts digital numbers to gamma-nought backscattering coefficients  $\gamma^0 = \sigma^0 / \cos \theta_{inc}$ , where  $\theta_{inc}$  is the local radar incidence angle, eliminating topography-induced illumination biases across steep terrain.

### F. Experimental Integrity and Rigorous Benchmarking Protocols

To prevent data snooping and information leakage, all few-shot support sets are sampled strictly from independent geographic tiles disjoint from the query evaluation set. Each experimental configuration is executed across 5 random seeds (seeds 42 through 46) with 50 Monte Carlo evaluation episodes per run. We report the exact empirical mean and standard error of the mean across all episodes. No hyperparameter tuning was conducted on the evaluation query sets.

TABLE II: Comprehensive Few-Shot Classification Accuracy (%) across Four Earth Observation Water Resources Benchmarks under  $n \in \{1, 2, 4, 8, 16\}$  Shots (Averaged over 5 Independent Random Seeds). **Bold** indicates the highest accuracy; underline denotes the second-highest.

| Benchmark Dataset | Method / Adaptation Paradigm               | 1-Shot       | 2-Shot       | 4-Shot       | 8-Shot       | 16-Shot      |
|-------------------|--------------------------------------------|--------------|--------------|--------------|--------------|--------------|
| EUROSAT WATER     | Zero-Shot Baseline                         | 55.49        | 55.49        | 55.49        | 55.49        | 55.49        |
|                   | ProtoNet                                   | 31.17        | 33.86        | 40.58        | 49.57        | 58.62        |

## VI. EXPERIMENTAL RESULTS & COMPARATIVE ANALYSIS

### A. Overall Benchmark Performance

Table II and Fig. 1 present the comprehensive benchmarking results across all eleven methods on the four water resources benchmarks. Key observations include:

- 1) **Decisive Transductive Superiority:** Across all datasets and shot regimes, transductive methods (TIM++, LC-TIM, RL-HydroFM) systematically outperform inductive baselines (LP++, ProtoNet, Tip-Adapter) by +10.2% to +24.6%, confirming the enormous benefit

of jointly utilizing unlabeled satellite query tiles during inference.

- 2) **Dynamic Graph Benefits in Extreme Low-Shot Regimes:** Across all four benchmarks, our proposed RL-HYDROFM and RL-HYDROFM+SAR consistently achieve state-of-the-art accuracy. The performance advantage over static LC-TIM is most pronounced in the 1-shot and 2-shot regimes (+3.5% on Sen12-Flood, +4.2% on Sentinel-2 Water Bodies). By dynamically reducing  $\kappa_i \rightarrow 1$  on ambiguous boundary tiles, our

Fig. 4: Empirical distribution of learned dynamic neighborhood cardinalities ( $\kappa_i$ ) across query samples. The policy autonomously assigns  $\kappa_i = 1$  to uncertain boundary outliers and  $\kappa_i \geq 8$  to homogeneous open water interiors.

Fig. 5: ADM optimization convergence dynamics: Top-1 query accuracy and total transductive loss  $\mathcal{L}_{\text{total}}$  as a function of iteration step  $t \in [1, 150]$ . RL-HYDROFM+SAR achieves rapid, stable convergence within 25 iterations.

policy avoids catastrophic label contamination.

- 3) **Multi-Modal Radar Routing Synergy:** RL-HYDROFM+SAR consistently achieves the highest overall accuracy (e.g., 76.67% on Sen12-Flood at 16-shot), proving that reinforcement-learned optical-SAR routing effectively disambiguates complex water signatures.

### B. Per-Class Diagnostic Performance Breakdown

Table III and Fig. 6 detail class-wise performance on the Sen12-Flood benchmark. In emergency disaster scenarios, false alarms in non-flooded areas and missed detections in inundated zones carry high operational costs. RL-HYDROFM+SAR achieves 75.4% F1 on *Flooded Inundation* (+17.2% over Zero-Shot, +6.2% over LC-TIM) and 78.9% F1 on *Permanent Water*, verifying that multi-sensor gating effectively distinguishes transient disaster water from baseline water bodies.

Fig. 6: Class-wise Macro-F1 score comparison on Sen12-Flood under 4-shot regime. RL-HYDROFM+SAR delivers balanced performance across both disaster inundation and non-flooded terrain.

TABLE III: Class-wise Precision (P %), Recall (R %), and Macro-F1 (F1 %) under 4-Shot Regime on Sen12-Flood Multi-Modal Benchmark.

| Method         | Flooded Inundation |             |             | Permanent Water |             |             | Non-Flooded |             |             |
|----------------|--------------------|-------------|-------------|-----------------|-------------|-------------|-------------|-------------|-------------|
|                | P                  | R           | F1          | P               | R           | F1          | P           | R           | F1          |
| Zero-Shot      | 56.4               | 60.1        | 58.2        | 62.8            | 66.3        | 64.5        | 63.5        | 56.8        | 59.9        |
| LP++           | 58.2               | 55.9        | 57.0        | 60.5            | 63.8        | 62.1        | 64.1        | 62.5        | 63.3        |
| TIM++          | 65.2               | 67.9        | 66.5        | 70.1            | 72.0        | 71.0        | 69.4        | 67.1        | 68.2        |
| LC-TIM         | 68.4               | 70.0        | 69.2        | 72.5            | 75.1        | 73.8        | 72.0        | 71.0        | 71.5        |
| RL-HYDROFM+SAR | <b>74.8</b>        | <b>76.0</b> | <b>75.4</b> | <b>78.2</b>     | <b>79.6</b> | <b>78.9</b> | <b>76.1</b> | <b>75.5</b> | <b>75.8</b> |

### C. Statistical Significance Testing

To confirm that observed improvements are statistically robust, we conducted two-tailed paired Student's  $t$ -tests across 50 Monte Carlo few-shot episodes between RL-HYDROFM+SAR and LC-TIM. On Sen12-Flood (4-shot), the paired  $t$ -statistic is  $t = 4.82$  ( $p < 0.0001$ ), demonstrating statistical significance at the 99.9% confidence level.

### D. Uncertainty Calibration and Decision Safety

Beyond raw accuracy, operational disaster management requires well-calibrated posterior probabilities. As shown in the radar evaluation profile of Fig. 2, RL-HYDROFM+SAR achieves an Expected Calibration Error (ECE) of only 0.042, compared to 0.118 for Zero-Shot and 0.089 for static LC-TIM. This substantial calibration improvement prevents overconfident misclassifications in transitional riparian buffer zones.

## VII. EXTENSIVE ABLATION STUDIES

### A. Systematic Empirical Ablations

Table IV provides a four-part systematic ablation study on the Sen12-Flood benchmark (4-shot):

- 1) **Part A (Component Breakdown):** Stepwise addition of dynamic  $\kappa_i$ , adaptive  $\lambda_{\text{LC},i}$ , and multi-modal SAR routing brings cumulative gains of +32.50% over ProtoNet and +3.67% over static LC-TIM.
- 2) **Part B (Action Space Cardinality):** Evaluating fixed  $\kappa \in \{1, 3, 5\}$  vs. discrete dynamic candidate sets confirms that the proposed  $\{1, 3, 5, 8, 12, 16\}$  achieves optimal accuracy (73.17%).

TABLE IV: Systematic Empirical Ablation Suite on Sen12-Flood Multi-Modal Benchmark (4-Shot Setting).

| Ablation Aspect                         | Configuration / Design Choice                                    | Top-1 Acc (%) | $\Delta$ Gain   |
|-----------------------------------------|------------------------------------------------------------------|---------------|-----------------|

- Part C (Reward Formulation):** Incorporating query mutual information ( $\hat{I}_{\alpha}$ ) and neighborhood consensus into the transductive reward function yields a +2.67% improvement over pure validation accuracy.
- Part D (ADM Steps & Latency):** Sweeping  $T \in [5, 300]$  iterations demonstrates that our closed-form ADM solver converges in under 25 iterations (57.9 ms per batch), proving exceptional real-time viability for operational flood response.

### B. Computational Efficiency & Latency Analysis

Table V provides a comprehensive resource profile. Because RL-HydroFM operates entirely over frozen foundation features without backpropagation into the vision transformers, peak GPU memory footprint remains under 1.86 GB, and total transductive optimization executes in 78.4 ms per 2500-tile batch.

### C. Cloud Degradation Resilience

Fig. 3 illustrates the cloud-resilience ablation on Sen12-Flood under progressive optical attenuation (0% to 80% cloud cover). While optical-only performance rapidly degrades, RL-HydroFM+SAR automatically increases the SAR gating weight  $\beta_{sar,i}$ , maintaining high accuracy even under heavy overcast conditions.

### D. Foundation Backbone Cross-Architecture Portability

To confirm that RL-HydroFM is agnostic to the specific foundation model architecture, we evaluated its adaptation capabilities when paired with RemoteCLIP ViT-B/32, SkyCLIP

ViT-L/14, and DINOv3 SAT-493M. Across all three backbones, RL-HydroFM consistently yields +4.1% to +5.8% accuracy gains over static transductive baselines, proving that the learned graph meta-controller transfers seamlessly across heterogeneous vision-language architectures.

## VIII. HYDROLOGICAL IMPLICATIONS & OPERATIONAL DISASTER RESPONSE

From an operational hydrological perspective, RL-HydroFM delivers four core capabilities for emergency response agencies (e.g., Copernicus Emergency Management Service, NASA Disaster Program, UN-SPIDER):

### A. Operational Disaster Management Workflows

In emergency rapid-mapping protocols, satellite scenes must be processed and delivered to first responders within minutes of downlinking. Traditional deep network fine-tuning requires minutes to hours of GPU computation and hundreds of localized labels. In contrast, RL-HydroFM executes entirely within 78.4 ms per 2500-tile scene on frozen foundation embeddings, enabling near-real-time flood vector generation for disaster coordination dashboards.

### B. Complex Wetland & Thin River Preservation

Hydrological features often exhibit fractal, non-Euclidean geometries, such as braided river deltas, narrow irrigation canals, and shallow wetlands. Enforcing a static  $\kappa = 5$  connects thin water pixels across dry banks, causing severe over-segmentation. By autonomously assigning  $\kappa_i = 1$  and  $\lambda_{LC,i} \rightarrow 0$  to isolated water features, RL-HydroFM preserves narrow watercourses without erosion.

### C. Edge Computing & Low-Power Deployment

With a memory footprint under 1.86 GB and zero-backpropagation architecture, RL-HydroFM is deployable on embedded edge platforms (e.g., NVIDIA Jetson AGX Orin) onboard satellites and tactical airborne surveillance drones for autonomous in-orbit flood detection.

### D. Coupled Hydrodynamic Modeling and Flood Routing Integration

In operational flood management, satellite-derived surface inundation extents serve as direct boundary conditions for 2D hydrodynamic hydraulic simulators (e.g., LISFLOOD-FP, HEC-RAS 2D, and Telemac-2D). These models solve the 2D Saint-Venant shallow water equations:

$$\frac{\partial h}{\partial t} + \frac{\partial(uh)}{\partial x} + \frac{\partial(vh)}{\partial y} = q_{\text{source}}, \quad (32)$$

where  $h$  is water depth,  $u, v$  are depth-averaged velocity components in Cartesian coordinates, and  $q_{\text{source}}$  represents lateral inflow or precipitation excess. Traditional binary thresholding introduces substantial geometric boundary artifacts, such as artificial levee breaks or disjoint channel disconnects, which

destabilize numerical solvers. By adaptively pruning cross-boundary edges via  $\kappa_i = 1$ , RL-HYDROFM generates topologically consistent inundation vectors that directly conform to natural terrain contours and digital elevation models (DEMs). This high boundary fidelity enables direct assimilation of satellite predictions into predictive hydraulic routing models without manual post-processing.

### E. Zero-Shot Cross-Basin Generalizability

Because state representation  $\mathbf{s}_i$  relies on normalized entropy, probability margins, and feature cosine geometries rather than absolute pixel radiometry, the trained Actor-Critic policy generalizes directly across diverse geographic basins (e.g., from European river basins to tropical Asian deltas) without fine-tuning.

### F. Environmental Justice and Transboundary Water Diplomacy

Accurate and impartial spaceborne water monitoring is critical for mitigating conflicts over shared water resources in transboundary river basins (e.g., the Nile, Mekong, and Indus river systems). By providing an open-source, reproducible, and verifiable methodology that operates without access to proprietary regional training labels, RL-HYDROFM democratizes advanced geospatial analytics for developing countries and international river basin authorities.

## IX. CONCLUSION

In this paper, we introduced RL-HYDROFM, a novel reinforcement-learned multi-source transductive foundation model framework for few-shot Earth observation and water resources monitoring. By replacing rigid heuristics with an Actor-Critic policy that dynamically optimizes neighborhood topologies, consistency trust weights, and multi-modal optical-SAR gating, RL-HYDROFM establishes a new state of the art in few-shot remote sensing.

The proposed framework completely eliminates backpropagation into large vision transformer backbones, achieving sub-second inference speeds (78.4 ms per 2500-tile batch) with a minimal memory footprint (1.86 GB). Extensive experiments on four water and flood benchmarks confirm superior accuracy, outstanding low-shot sample efficiency (+6.5% gain over static baselines), and all-weather cloud-penetrating resilience during extreme storm events. The complete source code, trained policy weights, and evaluation benchmark suites are publicly accessible at <https://github.com/farhansajid/RL-HydroFM>. Future research will extend this framework to pixel-level dense water segmentation, temporal drought forecasting, and foundation model distillation for nano-satellites.

## ACKNOWLEDGMENT

The authors thank the European Space Agency (ESA), NASA Earthdata, and the open-source geospatial community for providing public Sentinel-1 and Sentinel-2 satellite data archives.
